ABSTRACT. Experiments on progressive unidirectional freezing are conducted to determine the evolution in $\delta^D$ and $\delta^{18}O$ of successive water samples and ice layers taken during the course of freezing. Results indicate that this evolution takes place in a $\delta^D-\delta^{18}O$ diagram, along a straight line with a characteristic slope. This slope, different from that due to the precipitation effect, gives a fingerprint of the occurrence of a freezing or of a melting-refreezing process in the studied reservoir.

Introduction

Detailed studies of the relationships between isotopic species in ice and water have established that $\delta^D = \Delta^D + 10$ in fresh precipitation of all types and in most surface waters. In this equation, as in those presented in this paper, $\delta^D$ and $\delta^{18}O$ are expressed in parts per thousand of the standard mean ocean water (S.M.O.W.) with $\delta^H$ and $\delta^{18}O_\text{iso}$ equal to 896.6 and 0.5685, respectively. This trend, also valid for glacier ice, is recognized in the literature as being an important feature of the isotopic fractionation of water occurring during condensation or sublimation in simple equilibrium processes (Craig and others, 1963; Dansgaard, 1964); it is called the precipitation effect.

We have shown (Jouzel and Souchez, 1982) from practical studies of regelation ice and from theoretical studies, that, after melting and refreezing, ice samples lie on a straight line in a $\delta^D-\delta^{18}O$ diagram, with a slope different from that of the precipitation effect. This freezing effect has been developed theoretically for a closed system and applied to practical case. The aim of this paper is to test this model experimentally.

Experimental Approach

The changes during the course of freezing in $\delta^D$ and $\delta^{18}O$ of water samples and ice layers were determined by experiments on progressive unidirectional freezing.

In each experiment, 500 ml of water was progressively frozen downwards in a "Plexiglass" cylinder of approximate dimensions 10 cm h and 8 cm internal diameter (Fig. 1). Excess water produced during freezing was diverted through an adjacent tube and allowed to escape. The residual water was continuously stirred during freezing with a small magnetic stirrer; reasons for this stirring will be explained later. The freezing front moved downwards as a well-defined macroscopic plane. During each experiment, one millilitre of water was collected five times using a capillary tube inserted through the adjacent tube into the remaining water present in the cylinder.

Residual water was sampled at the beginning of the experiment, after 40%, 80%, 85%, 90% and 95% of the material had frozen. When the freezing process was complete, the ice core was recovered and sectioned. The samples covered the freezing ranges from 0 to 10%, 10 to 20%, 20 to 50%, 50 to 60%, 60 to 70%, 70 to 80%.

Fig. 1. The experimental vessel.
Three experiments were conducted with waters having very different initial isotopic composition: meltwater from an Antarctic ice core with an initial O value for deuterium of -40.8 ± 0.5‰ and an initial O value for 18O of -51.7 ± 0.1‰ (A), water from a small pond of Victoria Island in the Canadian Arctic with O = -153.2 ± 0.5‰ and C1 = -19.1 ± 0.0‰ (B), and water from a small Swiss pond near Grubengletscher with O = -109.1 ± 0.1‰ and C1 = -15.25 ± 0.0‰ (C).

Results of the experiments are indicated in Figure 2. The numbers quoted increase from the beginning of the experiment to the end: from 1 to 6 for the water samples and from 7 to 14 for the ice layers.

Three main points arise from Figure 2:

1. A progressive impoverishment of the heavy isotopes in both the residual water and the ice layers is clearly visible during the course of freezing.
2. Water and ice samples lie on a straight line. Using a least-square method, the slopes are respectively S = 4.37 ± 0.21 for the Antarctic meltwater, S = 5.99 ± 0.07 for the Arctic water, and S = 6.63 ± 0.17 for the alpine water. The correlation coefficients are always greater than 0.996.
3. The slope for the Antarctic melt water is lower than that for the Arctic water which is lower than that for the alpine water, in relation to the initial isotopic composition.

The closed-system model developed by Jouzel and Souchez (1982) gives a slope S

$$S = \frac{a - 1}{b - 1} \frac{1 + \delta_1}{1 + \Delta_1}$$

where a is the equilibrium fractionation coefficient for deuterium, b the same coefficient for 18O, \(\delta_1\) the O value of the initial liquid for deuterium and \(\Delta_1\) the O value of the initial liquid for 18O.

If we use \(a = 1.0208\) (Arnason, 1969) and \(b = 1.003\) (O'Neil, 1968), the calculated slopes are respectively 4.32 for the Antarctic meltwater, 5.99 for the Arctic water and 6.27 for the alpine water. Experimental slopes are thus well in accordance with predicted slopes from the model.

During the experiments, excess water due to the phase change was allowed to escape and this can be considered as an output. Moreover, the water constituting the reservoir can be schematically divided into two parts: a region, close to the interface, of constant volume which is isotopically modified by the freezing process, and a region, away from the interface, which is isotopically unchanged and which can be considered as input; additional ideas are needed to take this division into account. It is worthwhile considering a natural reservoir with input and output and to develop a theory to examine whether the predicted slopes in an open-system model are the same as those in the closed-system model which we have presented previously (Jouzel and Souchez, 1982).

THEORETICAL APPROACH

At time t, \(N_L\) is the number of moles in the liquid phase, \(N_A\) the number of moles in the solid phase, and

$$370$$
the number of moles which have entered the system since \( t = 0 \) as input, \( N_F \) the number of moles which have left the system since \( t = 0 \) as output, \( R_S = (1 + \delta_S) \) the isotopic ratio for \( D \) or \( { }^{18}O \) of the solid phase near the liquid-solid interface, \( R_L = (1 + \delta_L) \) the isotopic ratio of the liquid, \( R_a = (1 + \delta_a) \) the isotopic ratio of the input, and \( \alpha_{SL} \), the equilibrium fractionation coefficient between solid and liquid phases. Once formed, the solid has an isotopic composition which does not change in the course of time. At each step, the only isotope quantity (for \( D \) or \( { }^{18}O \)) brought to the solid phase is thus

\[
\alpha_{SL} R_L dN_S = \alpha_{SL} (1 + \delta_L) R_L dN_S.
\]

Now for an open system

\[
dN_L = dN_A - dN_S - dN_F \quad (1)
\]

and for the isotopes

\[
R_L dN_L + N_L dR_L = R_A dN_A - \alpha_{SL} R_L dN_S - R_L dN_F \quad (2)
\]

or

\[
(1 + \delta_L) dN_L + N_L d\delta_L = (1 + \delta_A) dN_A - \alpha_{SL} (1 + \delta_L) dN_S - (1 + \delta_L) dN_F, \quad (3)
\]

giving (on substituting \( dN_L \) for its value in (1))

\[
N_L d\delta_L = (\delta_A - \delta_L) dN_A - (\alpha_{SL} - 1) x (1 + \delta_L) dN_S. \quad (4)
\]

If we consider a constant input, a constant freezing rate, and an output proportional to the volume of remaining liquid, then

\[
dN_A = AN_0 dt,
\]

\[
dN_S = SN_0 dt,
\]

and \( dN_F = FN_0 dt \)

where \( A, S, \) and \( F \) are the respective coefficients for input, freezing, and output and \( N_0 \) is the number of moles in the reservoir at time \( t = 0 \). Now, if \( k = N_L/N_0 \)

\[
\alpha_{SL} - 1 (1 + \delta_L) = \frac{A}{S} (\delta_A - \delta_L) \]

\[
d\delta_L = \frac{k (1 + \frac{F}{S} - \frac{A}{S})}{\frac{A}{S} (\delta_A - \delta_L)} \]

This equation, applied to deuterium and \({ }^{18}O\) with the appropriate fractionation coefficient, gives the possibility by a step-by-step computation to calculate the \( \delta_O \) and the \( \delta^{18}O \) of the remaining liquid phase and of the solid formed during the freezing process. Results indicate that, whatever the values of \( F/S \) and \( A/S \) may be, the two phases evolve almost linearly on a \( \delta_D - \delta^{18}O \) diagram.

**DISCUSSION**

The open-system model developed above assumes a constant freezing rate but this is not the case in the experiments. However, the experimental results do not show a change of slope in the course of freezing in spite of the freezing-rate reduction. Moreover, the introduction of a time-dependent freezing rate in the model will make the computation more complicated but will have no effect on the slope.

If we now focus attention on the range between the ice (or residual water) value at 95% freezing and the initial value, the range in the experiments is less than that predicted by the closed-system model. The observed enrichment of the ice compared with the bulk of the liquid water depends on several parameters, particularly on the freezing rate and on the

\[
S = \frac{\alpha [\delta_a - (\delta_a - \delta)]}{\beta [\delta_A - (\delta_A - \delta_A)]} \quad (7)
\]

Equation (7) is independent of \( A, F, \) and \( S \) and almost identical to the equation obtained for the closed system. The slope will thus be the same for an open system as for the closed system when the input is not significantly different in its isotopic composition from that of the natural reservoir being considered.

**Fig. 3.** Relationship between apparent fractionation coefficients in the freezing experiments. Equilibrium values are respectively: \( \delta_{eq} D = 0.0098 \) and \( \delta_{eq}^{18}O = 0.003. \)
possible trapping of liquid during crystal growth. This dependency between the freezing rate and the observed fractionations is discussed in Posey and Smith (1957), O'Neil (1968), and Arnason (1969). As noted by Posey and Smith (1957), the observed separation will be less than the true value and the effect can be reduced by strong agitation and very slow freezing rates. Previous experiments without stirring led to correct slope values but to an even smaller range.

The following equation, equivalent to that which describes a Rayleigh process, was derived in the closed-system model:

\[
(1000 + \delta L) = (1000 + \delta I) \rho^{\delta L}
\]

where \( \delta L \) is the initial \( \delta \) value of the reservoir and \( \rho \) is the liquid fraction with \( \delta L \) and \( \delta I \) expressed in per mil. From this equation, we can compute the apparent \( \alpha \) and \( \beta \) values in the course of the three experiments. Apparent \( \alpha \) and \( \beta \) values depend on the freezing rate which is about 1.9 cm h\(^{-1}\) at the beginning of each experiment and close to 0.8 cm h\(^{-1}\) at the end.

In Figure 3, the apparent (\( \alpha - 1 \)) values are plotted versus the apparent (\( \beta - 1 \)) values in the three experiments for different liquid fractions. A straight line joins the zero point where there is no fractionation to the point where (\( \alpha - 1 \)) and (\( \beta - 1 \)) have their equilibrium values. From this Figure it is clear that the points are close to the straight line indicating that the slopes (\( \alpha \text{app}-1 \))/\( \beta \text{app}-1 \) in the experiments are not different from the equilibrium slope (\( \alpha -1 \))/(\( \beta -1 \)). It is quite probable that, for freezing rates encountered in nature, the slope \( S \) is always a characteristic of the freezing process, even if apparent fractionation coefficients have values lower than their respective equilibrium values.

The trapping of liquid water which subsequently freezes during crystal growth will lower the range but will have no effect on the slope since residual water samples and ice samples lie on the same straight line on a \( \delta D-\delta 18O \) diagram.

CONCLUSION

The amount of fractionation which takes place during natural processes cannot be known. Even in the simplest of conditions, during, for example, the freezing of water in a closed system with isotopic equilibrium (allowing the application of the Rayleigh model), ice layers can be either isotope-enriched at the beginning of the process or isotope-impooverished at the end, compared with the initial reservoir. Under natural conditions the problem is complicated by non-equilibrium processes, the trapping of liquid water, and also input and output of water to and from the reservoir. Thus, it is not possible to show whether a refreezing process has taken place in a reservoir from the measurement of only one isotope (\( \delta D \) or \( \delta 18O \)). It is the \( \delta D-\delta 18O \) slope which is characteristic of the freezing process, on the other hand. This has been shown to be the case, both experimentally and theoretically, in the present paper.

Such a study may have implications for research concerning ice-bedrock interface problems and may shed some light on the origin of ice masses either at the earth surface or in the ground.

ACKNOWLEDGEMENTS

We are very grateful to R. Chiron for stable-isotope measurements.
